

INFORMATION AGGREGATION BY VOTING[†]

Information Aggregation in Standing and Ad Hoc Committees

By S. NAGEEB ALI, JACOB K. GOEREE, NAVIN KARTIK, THOMAS R. PALFREY

In the last decade, Marie Jean Antoine Nicolas de Caritat Marquis de Condorcet's (1785) theory of committee decision making has emerged as a workhorse model in political economy, particularly voting theory. In its simplest modern formulation, the "Condorcet Jury Model" (CJM hereafter) features a committee of size n that is faced with a binary policy. The optimal policy is the same for all members, but depends on an unknown state of the world. Each member of the committee receives some private information about the state. The policy is determined by an election in which each voter can vote for either alternative, and the profile of votes is aggregated into a group decision according to some voting rule such as majority or unanimity with a status quo. The voting procedure also specifies the order in which voters cast their votes.

In this framework, one can compare voting behavior and informational efficiency under alternative voting rules and procedures, a methodology referred to as the *information aggregation approach to elections*. The past decade has produced a large and growing set of results on this topic, under various modifications to

the basic CJM.¹ This resurgence of interest in Condorcet's approach was sparked by a key observation of David Austen-Smith and Jeffrey Banks (1996) that "naive" voting is generally not a Nash equilibrium of the voting game. That is, the optimal way to vote in a multiperson committee is not usually the same as the optimal way to vote in a committee of one, an issue overlooked by Condorcet and other non-game-theoretic analyses of his model. In fact, a voter's strategic incentives generally depend on all the variables of the model: the size of the committee, the voting rule and procedure, the information structure, preferences, and so forth. Because such a simple model offers rich insights into the strategic considerations faced by voters, the CJM has played a prominent role in enhancing our understanding of voting mechanisms.

However, some of the equilibrium properties of these common value elections can be unintuitive. In a striking example of this, Feddersen and Pesendorfer (1998, FP hereafter) have shown that in the context of juries for criminal trials, requiring a unanimous vote for conviction may actually lead to more convictions than using majority rule. Because such theoretical predictions and the equilibrium strategies that underlie them are seemingly unnatural, they are particularly good candidates for empirical testing. Unfortunately, testing the theory with field data is virtually impossible because of the sensitivity of the results to the exact parameters of the model, and there are no obvious datasets available for such a purpose.² Consequently, in

² The closest would be some data on real jury voting, but the details of the information structure are not clear,

this paper, we adopt an experimental approach to understanding common value elections.

This paper examines two interrelated issues in the information aggregation approach to voting. The first question that we address is robustness. Since the goal of the theory is to provide a *general framework* to analyze voting in committees, is it the case that committees that are fundamentally different respond in similar ways to their asymmetric information? We address this question by comparing decision making under unanimity rule in *ad hoc committees*, like juries or expert panels, versus *standing committees*, like boards of directors, judicial panels, or town councils. An important difference between the two is that ad hoc committees have a short life and address a very limited set of issues (often only one, as with trial juries in the United States), whereas standing committees have a long life, and the members of the panel therefore engage in a repeated game. Hence, our first question is: do the theoretical predictions of the CJM apply equally well (or equally poorly) to the behavior of ad hoc committees and to the behavior of standing committees?

One reason to believe that there could be a difference is that the CJM usually has many equilibria. Broadly speaking, a common value election involves coordination among voters, and thus admits multiple equilibria which can be ranked by the Pareto criterion. Moreover, when committee members vote sequentially, there are asymmetries across voting positions that may be relevant to behavior. Indeed, it has often been suggested that sequential voting would give rise to *momentum* effects, where later voters tend to follow the choices of earlier voters. Recent theoretical work on this question by Eddie Dekel and Michele Piccione (2000) and Ali and Kartik (2007) has demonstrated that strategic voting in sequential elections can be both history-independent and history-dependent.³ This leads to the second question: can the timing structure of the voting procedure lead to selection of different equilibria?

and neither is the actual voting procedure used (since juries operate behind closed doors).

³ The aforementioned authors prove results for a wide class of voting rules, including unanimity rule, which is our focus here. In the context of majority rule, see also Jürgen Wit (1997), Mark Fey (2000), and Steven Callander (2007).

There have been only a few prior experimental studies of voting behavior in the CJM.⁴ The most relevant for us is the first study of strategic voting under unanimity rule, by Serena Guarnaschelli, Richard D. McKelvey, and Palfrey (2000, GMP hereafter). They found that, consistent with equilibrium predictions, committee members often voted strategically in the sense of sometimes casting a vote in contradiction to their private information about the state of the world. GMP also found that the comparative static predictions about the voter strategies under unanimity rule were qualitatively correct (more strategic voting in larger committees), although the changes in observed behavior were not as large as predicted by theory. An important consequence of this deviation from equilibrium strategies was that many of the predictions of FP with respect to information aggregation and efficiency were rejected by the data.

The GMP study considered only ad hoc committees that met once and then were dissolved. In the study reported here, we attempt to replicate their results with standing committees that meet repeatedly. Moreover, GMP considered only simultaneous voting. Here, we compare behavior under sequential and simultaneous voting procedures.

I. Experimental Design and Procedures

The laboratory study implemented several variations of the following game based on the CJM. There is a committee (e.g., a jury) with n members. Nature randomly chooses a payoff-relevant state of the world, ω , from the set $\Omega = \{G, I\}$, where “G” stands for Guilty and “I” for Innocent. Each state is chosen with equal probability. Members do not observe the selection of the state, but each member, j , receives a private signal, s_j , about the state. Each signal $s_j \in \{g, i\}$ is a conditionally independent Bernoulli random variable where $\Pr(s_j = g | \omega = G) = \Pr(s_j = i | \omega = I) = p > 1/2$. Each member j casts a vote $v_j \in \{c, a\}$ for one of two outcomes in $X = \{C, A\}$, where “C” stands for Convict and “A” for Acquit. There is no abstention. All the committees reported in this study operated under unanimity rule, which requires all n members to cast a c vote in order for C to be the committee

⁴ See Angela Hung and Charles R. Plott (2001), Krishna Latha, Gary Miller, and Joe Oppenheimer (2003), and Goeree and Yariv (2007).

decision. Members have identical preferences, which depend only on the group decision and the state of the world: $u(C, G) = u(A, I) = 1$, and $u(C, I) = u(A, G) = 0$.

Our experimental design has three treatment variables: committee size (n), committee type (ad hoc or standing), and voting procedure. We consider committees of two different sizes, $n = 3$ and $n = 6$, and two different voting procedures: simultaneous voting and sequential voting. Simultaneous voting is like a secret ballot, where individuals vote after receiving their private signals, but observing nothing else. In the sequential voting procedure, members vote one by one in a prespecified sequence, with each voter observing the votes (but not the private signals) of those before them. In the ad hoc committee treatment, subjects were randomly rematched into groups of size n at the start of each period. In contrast, in the standing committee treatment, subjects were randomly grouped at the start of the experiment, but the group composition remained constant during the entire experiment.

While our procedures are standard in experimental economics, there were several differences across treatments, including the subject pool, instructions, software, payoff salience, etc. The simultaneous ad hoc committee data are from the GMP study. The sessions for that study were conducted in 1997 and used 48 Caltech subjects who participated in 15 committees with unanimity rule.⁵ These sessions used a software program written in C++. The sequential ad hoc committee data were collected at UCLA in 2007, and in these experiments each subject participated in 30 committees. These sessions were conducted using the JAVA-based Multistage program (<http://multistage.ssel.caltech.edu>) and verbal instructions including overhead slides. Finally, the standing committee data were collected at UCLA in 2003, using a Virtual Basic program and online instructions.⁶ In these experiments, subjects made 30 committee decisions.⁷ The

three programs differed somewhat in the user interface for entering decisions. As we will show below, the experimental results seem to be quite robust to these variations in protocols and procedures.

In total, 222 subjects participated in the experiments (this includes the GMP subjects). Average earnings in the UCLA experiments were \$23.72, plus a fixed show-up payment; the experiments lasted somewhere between 40 and 60 minutes.⁸

II. Results

We focus our discussion of the experimental results mainly on the differences between ad hoc and standing committees, dividing the presentation between simultaneous and sequential voting. While we compare and contrast the behavior in different treatments, we do not explicitly test whether differences in behavior are statistically significant, because observations of group behavior are potentially correlated across rounds. Instead, the focus is on qualitative/economically substantive differences. We discuss this issue further in the final section of the paper.

A. Simultaneous Voting Procedure

First we ask: is behavior different between ad hoc committees and standing committees operating under unanimity rule with simultaneous voting? The top part of Table 1 answers that question with a clear *no* in terms of aggregate behavior. It reports the fraction of observations where individuals voted to convict in each treatment, broken down by whether they had received an innocent or guilty signal. The number of observations is shown in parentheses. The last two rows of Table 1 show the predicted frequencies of the unique responsive symmetric equilibrium, in which voters with guilty signals always vote to convict, and voters with innocent signals vote to convict with probability $\sigma^*(n) \in (0, 1)$.⁹ There is essentially no difference between ad hoc and

⁵ Each of these subjects also participated in additional committees with different voting rules and procedures, data that we do not use in this paper. See Serena Guarnaschelli, Richard D. McKelvey, and Palfrey (2000) for details.

⁶ We would like to thank Jos Theelen for programming the standing committee experiments.

⁷ In the UCLA experiments, subjects were recruited by mass e-mail invitations to registered members of a large subject pool of UCLA students, maintained by the California Social Science Experimental Laboratory.

⁸ In the UCLA sessions, subjects earned \$1.00 for each correct committee decision and \$0.10 for each incorrect committee decision. In the GMP experiment, subjects earned \$0.50 for each correct decision and \$0.05 for each incorrect decision.

⁹ "Responsive" means that a voter's behavior is not independent of his signal. The GMP study used slightly more informative signals (0.70 compared to 0.67). This results in negligible differences in the equilibrium, $\sigma^*(n)$, as seen in the bottom two rows of Table 1.

TABLE 1—FREQUENCY OF VOTES TO CONVICT BY SIGNAL
(Number of observations in parentheses)

	Committee size = 3		Committee size = 6	
	Guilty signal ($s = g$)	Innocent signal ($s = i$)	Guilty signal ($s = g$)	Innocent signals ($s = i$)
Simultaneous voting				
Ad hoc committee	0.95 (174)	0.36 (186)	0.90 (186)	0.48 (186)
Standing committee	0.94 (338)	0.35 (382)	0.94 (464)	0.52 (616)
Sequential voting				
Ad hoc committee	0.97 (231)	0.39 (200)	0.93 (317)	0.62 (286)
Standing committee	0.98 (202)	0.44 (129)	0.98 (287)	0.50 (262)
Symmetric equilibrium				
$p = 0.7$	1	0.31	1	0.65
$p = 0.67$	1	0.32	1	0.66

standing committees in the probability of voting to convict with either a guilty or innocent signal when $n = 3$, and only a negligible difference when $n = 6$. We conclude that the findings of GMP are replicated almost exactly using standing committees instead of ad hoc committees (and all the other procedural differences). Note that there is clear evidence of at least some strategic voting: regardless of treatment, a significant fraction of subjects votes to convict with an innocent signal. In the $n = 3$ cases, the fraction is a bit higher than equilibrium predicts, whereas in $n = 6$, it is lower. In both ad hoc and standing committees, the predicted comparative static, that $\sigma^*(n)$ increases with n , is observed.

Second we ask: is information aggregation different in ad hoc committees and standing committees? Because standing committees allow greater opportunities for coordination, one may conjecture that such committees will aggregate information more efficiently than ad hoc committees. The top part of Table 2 shows the proportion of correct group decisions (convicting the guilty or acquitting the innocent). On the whole, we see, at best, limited support for this conjecture. In particular, there is virtually no difference in information aggregation between ad hoc and standing committees when $n = 6$. When $n = 3$, ad hoc committees do better than standing committees in the G state, and worse in the I state: overall, the fraction of correct decisions in the ad hoc committees is 57 percent, whereas it is 64 percent for standing committees. These numbers can be compared with the predictions of the symmetric equilibrium and an efficient equilibrium, i.e., the one that maximizes the committee's welfare, shown in the bottom two rows in Table 2. The

efficient equilibrium highlighted in Table 2 is an asymmetric equilibrium where two voters vote informatively (i.e., "vote their signal"), and all remaining voters convict regardless of signal.¹⁰

B. Sequential Voting Procedure

We now turn to our sequential voting treatments, where votes are cast publicly one after another. First we ask: is behavior different between ad hoc committees and standing committees operating under unanimity rule with sequential voting? To address this question, we examine only those observations in which a voter does not already know the outcome of the election, i.e. every preceding voter has voted to convict so far. This is appropriate because once a voter votes to acquit, each subsequent voter is indifferent between voting to convict and voting to acquit.

The bottom part of Table 1 lists the aggregate frequencies with which subjects vote to convict given each signal for such *undecided histories*. This can be compared with the symmetric, history-independent equilibrium of the sequential voting game (bottom row), which simply replicates the symmetric equilibrium of the simultaneous game, an insight due to Dekel and Piccione (2000). The only substantial difference across committee types is in the six-person treatments

¹⁰ For our parameters, an alternative equilibrium in which one voter votes informatively and all remaining voters vote to convict attains the same expected payoffs as the efficient equilibrium we describe in Table 2. In this alternative equilibrium, convictions in the guilty state occur with the same probability as acquittals in the innocent state, a feature not shared by our experimental data in any treatment.

TABLE 2—CORRECT DECISIONS BY STATE
(Number of observations in parentheses)

	Committee size = 3		Committee size = 6	
	Convicting guilty	Acquitting innocent	Convicting guilty	Acquitting innocent
Simultaneous voting				
Ad hoc committee	0.47 (57)	0.81 (63)	0.27 (26)	0.97 (34)
Standing committee	0.39 (132)	0.94 (108)	0.27 (83)	0.99 (97)
Sequential voting				
Ad hoc committee	0.35 (167)	0.79 (106)	0.38 (210)	0.87 (150)
Standing committee	0.50 (113)	0.78 (97)	0.33 (101)	0.87 (79)
Symmetric equilibrium				
$p = 0.7$	0.50	0.86	0.52	0.81
$p = 0.67$	0.46	0.84	0.48	0.79
Efficient equilibrium				
$p = 0.7$	0.49	0.91	0.49	0.91
$p = 0.67$	0.44	0.89	0.44	0.89

under innocent signals. In this case, subjects in standing committees convict significantly less than in ad hoc committees. In the remaining three cases, there are only small differences ($n = 3, s = i$ and $n = 6, s = g$) or virtually none ($n = 3, s = g$). Overall, at this aggregate level, the behavior of ad hoc committees is closer to the predictions of the symmetric equilibrium.

Second we ask: is information aggregation different in ad hoc committees and standing committees? Here, we do find some support for the conjecture that standing committees would aggregate information more efficiently than ad hoc committees, although only for the smaller committee size (see Table 2). For the six-person committees, there are only slight differences in the probability of making the right decision conditional on each state. For the three-person case, standing committees appear to do significantly better than ad hoc committees in the G state, but do approximately well in the I state: overall, the fraction of correct decisions in the ad hoc committees is 52 percent, whereas it is 63 percent for standing committees. Again, these aggregate percentages can be compared with the predictions of the symmetric and efficient equilibrium that are listed in the bottom two rows of Table 2.

III. Discussion

A remarkable feature of our data is the consistency or robustness across treatments. Recall that the data were collected at various points in time, using different subject pools, software, instructions, etc., and by different experimenters. Yet many features of the data, e.g., the tendency to

vote strategically after having received an innocent signal, are similar across treatments, both in qualitative and quantitative terms. Furthermore, we find only minor differences between ad hoc and standing committees, suggesting that repeated interactions do not necessarily lead to the selection of different equilibria.

While it is desirable to test whether the differences across treatments are statistically significant, a challenge is that observations of group decisions are not independent across rounds. To illustrate: in the standing committee decisions, the past behavior by members of a group may influence a subject's future behavior, thereby making the group's decisions across rounds correlated. While the question of significance is important, and one that we hope to address rigorously in future work, the similarity of both behavior and aggregate outcomes across ad hoc and standing treatments is striking.

Interestingly, there are some differences between the simultaneous and sequential treatments that suggest the possibility of information cascades or momentum effects under the sequential voting procedure. Consider, for instance, the fraction of correct outcomes for a committee of size six (see the right-most two columns of Table 2). Note that sequential voting results in a higher percentage of convictions in both the innocent and guilty states, possibly because later voters with innocent signals mimicked predecessors who voted to convict. Indeed, although we do not report it here, the data show that this is often the case.

In future work, we plan to analyze how voting strategies vary with the voter's position

under the sequential protocol. In particular, we will compare the history-independent symmetric equilibrium (Dekel and Piccione 2000) with the history-dependent posterior based voting (PBV) equilibrium proposed by Ali and Kartik (2007).¹¹ Obviously, in the data there are some deviations that cannot be described by either equilibrium, and we will employ a logit-QRE framework to allow for a maximum likelihood comparison of history-dependent and history-independent voting.

¹¹ As Dekel and Piccione (2000) have pointed out, in unanimity games, the set of responsive equilibria is identical under sequential and simultaneous voting. Nevertheless, the inherent asymmetry of positions in a sequential procedure may make coordination on some asymmetric equilibria—such as PBV equilibria—more salient. Moreover, we also plan to use majority rule data, where there are sequential voting equilibria that are distinct from any simultaneous voting equilibrium.
